(Received 31st Jan 2017; accepted 20th Jul 2017)

Abstract. The article shows the practical value of biogas as the second generation biofuel. All the projects dealing with biogas are subjected to external risks, such as the change of market condition, customer needs, governmental regulation, etc. In conditions of uncertainty it is necessary for administration to concentrate on decision-making. Fluctuations of sales volume, energy resources and raw material prices, etc. should be taken into account. Sensitivity analysis can predict the result of negative external phenomena. We developed the economic-mathematical model for the analysis of biogas complexes sensitivity. The profitability index as a criterion for the effectiveness of investment projects is a special feature in this model. The calculations show that biogas optimal distribution provides much larger gross income. We also suggested the methodology for sensitivity analysis implementation in investment projects for biogas complex creation. According to our calculations, the most stable project has utilization both biomethane (as motor fuel) and carbon dioxide. We demonstrate that the use of the profitability index as a criterion for an investment project gives higher critical values of input external factors, that endows assured profitability of an investment project.

Keywords: *biomethane, profitability index, net present value, critical point, carbon dioxide, motor fuel*

Introduction

Exhaustible fossil energy resources and ecological problems are among the major threats of modern civilization. Therefore, nowadays there are acute problems such as efficient use of traditional energy resources, implementation of energy-saving technologies, reduction of energy production intensity and the use of alternative energy resources including renewable ones (Brower et al., 2006; Stern, 2007).

Science has developed and used the civilizational approach to the understanding of the history of mankind. The transition from one stage of civilization maturity to another takes place due to deep qualitative changes of productive forces of the society and growth of labor productivity. These changes are impossible without an increase in the use of energy resources.

In the researchers' opinion, the power engineering is developed as follows (*Fig. 1.*):

- reducing energy intensity of production;
- increased use of fossil energy resources, which reserves exceed the reserves of petroleum;

- the use of renewable energy sources;
- the use of energy resources has to comply with environmental standards.

Since the end of the twentieth century, there has been a tendency to reduce the use of hydrocarbon fossil fuels due to intensive utilization of renewable energy, including biofuels. Therefore, there has been a spiral trend in the use of energy at a higher technological level. In ancient times, biofuels were used in the primary form (wood or agricultural waste), but nowadays they are mainly utilized in a more convenient, processed form such as briquettes, liquid or gaseous biofuels.

The first generation biofuels are produced from crops. As a result, it decreases food producing. More than one billion people are starving regularly worldwide. In 2008 this fact forced the United Nations to appeal to suspend production of biofuels from crops which can be used for food (LSB, 2013). Thus, production of the second-generation biofuels (from non-food plant resources) is a promising direction. It will not increase the deficit of food crops (Patyka et al., 2016). Animal and crop waste, municipal and industrial waste water, solid waste landfill are substrates for biogas production. Such gaseous biofuel can be used as a substitute for natural gas and motor fuels. Therefore, biogas production is an encouraging step forward.

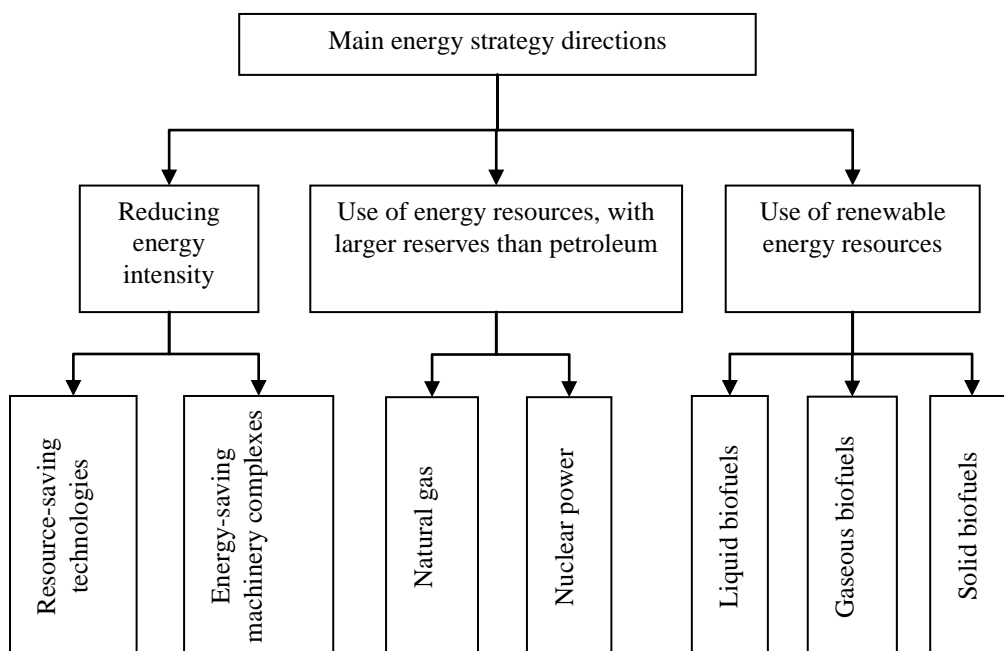

Figure 1. Main energy strategy directions in power engineering

A significant number of countries are increasing biogas production (ePURE, 2014; Alberici and Toop, 2013). Thus, in China, biogas production has reached 15 billion m³ per year. This equals about 7,5 million tons of oil equivalent. Furthermore, in the EU, biogas production exceeds 13 million tonnes of oil equivalent (EBA, 2013).

Moreover, biogas meets recent environmental requirements. In accordance with the requirements of the Directive 2009/28/EC, reduction of greenhouse gas emissions in the implementation of renewable energy technologies should be at least 35% compared to fossil fuels use. Biogas use reduces greenhouse gas emissions by 56-86%, depending on

the substrate and way of its utilization. This renewable gaseous fuel meets the requirements of the second generation biofuels (Geletukha et al., 2014). Thus, biogas production and use can be an attractive investment. Its use allows both to meet the requirements of the post-industrial society and make a significant contribution to the energy security.

All investment projects, including building of biogas plants, are subjected to risks. They are forced with uncertainty. It is a result of a lack of firm data concerning conditions and parameters of investment project implementation. The administration should focus on making decisions to achieve maximum profitability in the condition of uncertainty. Therefore, it is necessary to assess the impact of negative external factors on effectiveness of an investment project (Pikler, 2014).

Evaluation of investment projects is possible while applying different methods, such as the break-even analysis, sensitivity analysis, scenario method, theory of games, decision-making theory, etc. One of the simplest and most effective methods is sensitivity analysis. This analysis is a calculating procedure used to predict the impact of input data on output results of a project. This procedure is often used for investment decision-making related to investment project evaluation in conditions of uncertainty (Adler, 1987; Kalinichenko et al., 2016). However, the methodology of sensitivity analysis for investment projects of biogas producing is still not developed enough and needs to be investigated.

The aims of this study were to clarify the procedural technique for the sensitivity analysis of a biogas plant investment project, determine the degree of input values set influence on their cost-effectiveness and reveal the difference in results for the accepted criteria: *NPV* and *PI*.

Literature Review

One of the challenges for the biofuel industry, including biogas plants, is the high level of uncertainty. These uncertainties complicate the assessment of investment decisions (Kim et al., 2011). The input variables are regarded as uncertain. These are the investment costs, discount rate, sale prices, sales volume, economic plant life, etc. The sales volume consists of electricity, heat, fertilizer, biomethane, by-product (carbon dioxide). They are every year changeable and dependent from the current market prices. Both the achievable sales volume and the selling price are uncertain (Blohm, 2006; Hoffmeister, 2008; Pikler, 2014).

The sensitivity analysis is suitable if there is no statistical data. It allows us to identify factors on which managers' attention should be focused during project implementation (Willem and Groenendaal, 1998; Borgonovo and Peccati, 2004). The purpose of the sensitivity analysis is selecting "critical" variables of the model which have the biggest influence on the criteria of an investment project and cause the most significant changes in these parameters.

The theoretical risk classification, assessment methods and risk management have been studied by a number of scientists. The analysis of these works shows that the risk is a complex, multifaceted phenomenon. There are different interpretations of the concept.

The studies were focused both on the general sensitivity analysis of investment projects and the risk in general (Milanović et al., 2010; Burja and Burja, 2009; Analti, 2003; Jovanovic, 1999). The sensitivity analysis is a mandatory attribute of the financial analysis of energy projects.

Federica Cucchiella and Indiano de D'Amado have evaluated financial feasibility of biomethane plants and proposed a mathematical model. The Net Present Value and Discounted Payback Period are the indicators of the above. The sensitivity analysis on the critical variables was also conducted (Cucchiella and D'Amado, 2016). General aspects of the sensitivity analysis were studied by Mirela Iloiu and Diana Csiminga. In their research, viability of investment projects are based on the Internal Rate of Return (*IRR*) and Net Present Value (*NPV*) criteria (Iloiu and Csiminga, 2009).

Despite the number of studies (Menind and Olt, 2009; Kossmann et al., 2009; Pingping, 2010; Arnórsson, 2011), the sensitivity analysis is still not very well understood and this reduces the quality of management decisions. The sensitivity analysis of biogas projects is used to facilitate decision making under uncertainty. This can provide an adequate insight into the possible problems for the decision maker (Mészáros, 2014).

Peter Jovanovic considered the Net Present Value, Internal Rate of Return and Payback Period as criteria of investment projects (Jovanovic, 1999). In the authors' previous study, only *NPV* was accepted as a criterion (Gavriš and Perebijnos, 2015). The *NPV* is an absolute criterion, which cannot give an unambiguous answer about a project's suitability. In our opinion, the Profitability Index (*PI*) is a more appropriate criterion. That is why both *NPV* and *PI* criteria are used for this study.

Research Methodology

The methods used in this study include on-site data collection and literature review. The on-site data collection includes technical information about biogas plants accumulating, their efficiency, risk and uncertainty. The literature review helps to do a financial analysis.

First of all, we defined a set of criteria as a basis for the investment project evaluation. The assessment of an investment project is actually based on an estimation of future cash-flows. We also selected and identified a set of input key factors.

The resulting calculations are the values of individual criteria determining the values of certain input variables to determine the maximum (or minimum) values that certain variables can take if the investment project remains profitable. Finally, the results were analyzed and interpreted. It helps us to prevent or remove adverse impacts and make certain improvements.

Mathematical Model Development

In this study, the net present value and profitability index were chosen as criteria of the investment project. The *NPV* and *PI* have been selected as they are the main parameters for investors while making decisions.

The *NPV* is a difference between the present value of cash inflows and present value of cash outflows. The profitability index is a ratio of payoff to investment of a suggested project. It allows to quantify an amount of value created per unit of investment. If the *PI* is more than 1.2, a project is acceptable.

The sensitivity analysis procedure is as follows:

- identify all the variables used to calculate the output of economic analyses;
- carry out a qualitative analysis for an impact of the variables in order to select those having little or marginal elasticity;
- having chosen the significant variables, it is possible to evaluate their elasticity;

- identify the critical variables, apply the chosen criterion.

In the investment project evaluation, there is a set of input values (income, costs, discount rate, value of investments, etc.) and a set of output ones (*NPV* and *PI*). Having used the input values, it is possible to determine certain individual output values (*Fig. 2*) (Stone, 1988).

Figure 2. Calculation of individual criteria using input and output values

Let us analyze the critical points, i.e. determine the level of project-specific factors leading to the zero net present value. With respect to the biogas plant, the *NPV* is defined by the following formula

$$NPV = \sum_{i=1}^n \frac{GI_i - OC_i}{(1+d)^i} - \left(I_0 + \sum_j \frac{I_{aj}}{(1+d)^{T_j}} \right), \quad (\text{Eq. 1})$$

where GI_i is a gross revenue from the biogas plant operation (use of electrical energy, thermal energy, biomethane as motor fuel, carbon dioxide, manure, etc.) in the i^{th} time period, EUR; OC_i is operating expenses in the i^{th} period, EUR; d is the discount rate; n is the economic plant life, years; I_0 is the initial cost of the total investment, EUR; I_{aj} is a the cost of the j^{th} additional investments, EUR; T_j is time of the j^{th} additional investment, years.

While projects are planned to operate and be efficient for a time period of approximately 20 - 25 years, we assume that their plant life is 20 years (Gkamplia et al., 2012; Henning, 2011). But a depreciation period of some equipment (pumps, stirrers, heating system, combined heat and power generation, etc.) is shorter and is about 7 - 10 years (Henning, 2011). So, additional investments are made to renovate some equipment with shorter lifetimes.

As for the profitability index, its value should not be less than 1.2

$$PI = \frac{\sum_{i=1}^n \frac{GI_i - OC_i}{(1+d)^i}}{\left(I_0 + \sum_j \frac{I_{aj}}{(1+d)^{T_j}} \right)} \geq 1.2 \quad (\text{Eq. 2})$$

Next, we will consider three ways of biogas utilization with:

- combined heat and power generation;
- motor fuel replacement;

• motor fuel substitution and carbon dioxide use (resulting in biogas upgrading).
 We propose to study an impact of the following major risk factors:

- the initial investment value;
- the additional investments value;
- the substrate cost;
- the biogas plant load factor;
- the discount rate;
- the actual biogas plant life;
- biogas plant operating expenses;
- revenue from electric power sale;
- revenue from heat sale;
- revenue from biogas (biomethane) sale (as motor fuel);
- revenue from carbon dioxide (by-product of biogas upgrading) sale.

The factors having a low variation are the most risky elements of the investment project. The relative deviation of each factor is determined as follows:

$$\Delta F = \frac{F_{cr} - F_o}{F_o} \cdot 100\% \quad (\text{Eq. 3})$$

where F_o is the influence factor value established according to the initial prognosis;
 F_{cr} is the critical influence factor value.

To determine the degree of influence of each factor on the net present value, we should to determine the elasticity coefficient. Therefore, we use the following formulas:

$$E_{NPV/F} = \frac{dNPV / NPV}{dF / F} \quad (\text{Eq. 4})$$

or

$$E_{PI/F} = \frac{dPI / PI}{dF / F} \quad (\text{Eq. 5})$$

These expressions determine the elasticity at a particular point. In many cases (including dependence of the linear model), elasticity is different at various points. Thus, it is advisable to calculate the average value of the elasticity coefficient as a ratio of percentage changes in NPV , PI and F

$$E_{NPV/F} = \frac{\overline{\Delta NPV / NPV}}{\overline{\Delta F / F}} \quad (\text{Eq. 6})$$

or

$$E_{NPV/F} = \frac{\overline{\Delta PI / PI}}{\overline{\Delta F / F}} \quad (\text{Eq. 7})$$

Having taken into account that (for NPV)

$$\begin{aligned}\Delta NPV &= NPV(F_{cr}) - NPV(F_o), \\ \Delta F &= F_o - F_{cr}, \\ \bar{F} &= 0,5 \cdot (F_o + F_{cr}), \\ \overline{NPV} &= 0,5 \cdot (NPV(F_o) + NPV(F_{cr})),\end{aligned}$$

we get the final expression for the elasticity coefficient (for NPV)

$$E_{NPV/F} = \frac{(NPV(F_{cr}) - NPV(F_o)) / (NPV(F_o) + NPV(F_{cr}))}{(F_{cr} - F_o) / (F_o + F_{cr})} \quad (\text{Eq. 8})$$

A positive value of the elasticity coefficient indicates the coincidence of trends of both factors and the net present value, and a negative one – that the directions of the changes of a factor and NPV have different signs. In equation (1) at the critical point $NPV(F_{cr}) = 0$. If $NPV(F_{cr}) = 0$, then the elasticity factor is

$$E_{NPV/F} = \frac{(0 - NPV(F_o)) / (NPV(F_o) + 0)}{(F_{cr} - F_o) / (F_o + F_{cr})} = -\frac{F_o + F_{cr}}{F_{cr} - F_o} \quad (\text{Eq. 9})$$

Similarly, we obtain the expression for the profitability index

$$E_{PI/F} = \frac{(PI(F_{cr}) - PI(F_o)) / (PI(F_o) + PI(F_{cr}))}{(F_{cr} - F_o) / (F_o + F_{cr})} \quad (\text{Eq. 10})$$

In equation (2) at the critical point $PI(F_{cr}) = 1.2$.

Sensitivity Analysis Procedure

Performing the sensitivity analysis procedure involves the study of changes in the indicator, considering the remaining constants. If we take into consideration that the additional capital investments are made once in a biogas plant lifetime, the equation (1) is simplified and takes the following form

$$NPV = \sum_{i=1}^n \frac{GI_i - OC_i}{(1+d)^i} - \left(I_0 + \frac{I_{aj}}{(1+d)^{T_j}} \right) \quad (\text{Eq. 11})$$

If we assume that there is a regular cash flow, the annual return will be

$$R_0 = GI_i - OC_i = const \quad (\text{Eq. 12})$$

So,

$$NPV = \sum_{i=1}^n \frac{GI_i - OC_i}{(1+d)^i} - \left(I_0 + \frac{I_{aj}}{(1+d)^{T_j}} \right) = R \cdot \sum_{i=1}^n \frac{1}{(1+d)^i} - \left(I_0 + \frac{I_{aj}}{(1+d)^{T_j}} \right) \quad (\text{Eq. 13})$$

Let us determine the critical point, i.e. the value of specific factors leading to zero net

present value.

All the factors influencing the project effectiveness can be divided into two groups: the first group includes general ones (independent on technological features of the investment project) and the second group (dependent on technology). The values of the initial investment, additional capital investment, lifetime, discount rate belong to the first group. The values of the biogas plant load factor, revenue from energy resources (biomethane, electric and heat power) and carbon dioxide sale belong to the second group.

The actual investment costs may deviate from the established ones according to the initial prognosis. They may be a result of tax legislation amendments, for example. The critical value of the initial investment is

$$I_{cr} = R_0 \cdot \sum_{i=1}^n \frac{1}{(1+d)^i} - \frac{I_{aj}}{(1+d)^{T_j}} \quad (\text{Eq. 14})$$

where R_0 is the annual return according to the initial prognosis.

Such substitution can be made in case of constant difference in the gross income and operation expenditure during the project lifetime.

The critical value of additional investment is

$$I_{ajcr} = (1+d)^{T_j} \cdot \left(R_0 \cdot \sum_{i=1}^n \frac{1}{(1+d)^i} - I_0 \right) \quad (\text{Eq. 15})$$

The critical value of the annual return is

$$R_{cr} = \frac{\left(I_0 + \frac{I_{aj}}{(1+d)^{T_j}} \right)}{\sum_{i=1}^n \frac{1}{(1+d)^i}} \quad (\text{Eq. 16})$$

The critical value of the project lifetime can be determined as the discounted payback period (provided it is shorter than the additional investment period). If we take into account that

$$\sum_{i=1}^n \frac{1}{(1+d)^i} = \frac{1-(1+d)^{-n}}{d} \quad (\text{Eq. 17})$$

the discounted payback period is equal to

$$T_{cr} = DPP = - \frac{\ln \left(1 - d \cdot \frac{I_0 + \frac{I_{aj}}{(1+d)^{T_j}}}{R_0} \right)}{\ln(1+d)} \quad (\text{Eq. 18})$$

The critical value of the discount rate is found from the equation

$$0 = \sum_{i=1}^n \frac{R_0}{(1+d_{cr})^i} - \left(I_0 + \frac{I_{aj}}{(1+d_{cr})^{T_j}} \right) \quad (\text{Eq. 19})$$

where d_{cr} is the critical value of the discount rate.

The root of the equation (19) is found numerically. In fact, the critical value of the discount rate is equal to the internal rate of return, i.e. $d_{cr} = IRR$.

Let us consider the factors that are directly determined by the parameters of the biogas plant and its products. A gross income from the biogas plant operation and all related costs are determined as follows. Based on this, we consider the impact of the following factors on the project effectiveness: the substrate cost, operating expenses, heat and electricity use, biomethane use to replace conventional motor fuel (gasoline or diesel), carbon dioxide use.

The substrate cost is equal to

$$SC = M_s \cdot S_{pr} \quad (\text{Eq. 20})$$

where M_s is the annual consumption of the substrate, ton; S_{pr} is the substrate price (production cost), EUR/t.

The critical value of the substrate price (production cost) can be found from the following formula

$$R_0 - R_{cr} = M_s \cdot (S_{pr_0} + (S_{pr_{cr}} - S_{pr_0})) \quad (\text{Eq. 21})$$

where S_{pr_0} is the substrate price (production cost) in the base case, EUR/t; $S_{pr_{cr}}$ is the critical value of the substrate price (production cost), EUR/t.

So, the critical value of the substrate price (production cost) is

$$S_{pr_{cr}} = \frac{R_0 - R_{cr}}{M_s} = \frac{R_0 - \frac{\left(I_0 + \frac{I_{aj}}{(1+d)^{T_j}} \right)}{\sum_{i=1}^n \frac{1}{(1+a)^i}}}{M_s} \quad (\text{Eq. 22})$$

The critical value of operating expenses is

$$OC_{cr} = GI - \frac{\left(I_0 + \frac{I_{aj}}{(1+d)^{T_j}} \right)}{\sum_{i=1}^n \frac{1}{(1+d)^i}} \quad (\text{Eq. 23})$$

Let us consider three possible options of the biogas plant project. A company (a founder of the biogas plant project) may consume both heat and electric energy. Three options of biogas utilization have been considered:

- the company's energy requirements are covered with heat and electric energy produced by biogas plants;
- upgraded biogas (biomethane) is used as motor fuel (instead of petroleum fuels), carbon dioxide (a by-product of upgrading) is not used;
- both upgraded biogas (biomethane) and carbon dioxide are utilized or sold at the market price.

Biomethane and carbon dioxide are primary meant to be sold externally.

The gross income for the first option is determined as follows:

$$GI = W_e \cdot E_{pr} + Q_e \cdot H_{pr} + M_m \cdot M_{pr} \quad (\text{Eq. 24})$$

where W_e is electric energy production and use, kWh; Q_e is heat energy production and use, kWh; E_{pr} is the electric energy price, EUR/kWh; H_{pr} is the heat price, EUR/kWh; M_m is the annual manure production, t; M_{pr} is the manure price, EUR/t.

So, the critical values of the electricity and heat consumption will be

$$W_{e\ cr} = W_e - \frac{R_o - R_{cr}}{E_{pr}} \quad (\text{Eq. 25})$$

and

$$Q_{e\ cr} = Q_e - \frac{R_o - R_{cr}}{H_{pr}} \quad (\text{Eq. 26})$$

The critical value of the manure utilization volume is

$$Mm_{cr} = Mm_o - \frac{R_o - R_{cr}}{M_{pr}} \quad (\text{Eq. 27})$$

The equation for determining the gross income in the second option is

$$GI = V_b \cdot \frac{Q_b}{Q_f} \cdot F_{pr} + MS \cdot S_{pr} \quad (\text{Eq. 28})$$

where F_{pr} is the motor fuel price, EUR/liter; V_b is annual biogas production according to the initial prognosis, m³; Q_b is lower heat values of biogas, MJ/m³; Q_f is lower heat values of motor fuel, MJ/kg.

The critical value of biogas volume (in the form of biomethane) to substitute petroleum motor fuels is

$$V_{bcr} = V_{b0} - \frac{R_0 - R_{cr}}{F_{pr}} \cdot \frac{Q_f}{Q_b} \quad (\text{Eq. 29})$$

The equation to determine the gross income in the third option is

$$GI = V_b \cdot \frac{Q_b}{Q_f} \cdot F_{pr} + 0,01 \cdot \xi \cdot V_b \cdot CD_{pr} + M_m \cdot M_{pr} \quad (\text{Eq. 30})$$

where V_{b0} is annual production of biogas according to the initial prognosis, m^3 ; ξ is carbon dioxide content in biogas, %; CD_{pr} is the carbon dioxide price, EUR/1.

The critical value of biogas volume (in the form of biomethane) to substitute petroleum motor fuels is determined by the formula (30), and the volume of carbon dioxide sale is

$$V_{cdcr} = 0,01 \cdot \xi \cdot V_{bcr} = 0,01 \cdot \xi \cdot V_{b0} - \frac{R_0 - R_{cr}}{CD_{pr}} \quad (\text{Eq. 31})$$

If the maximum possible change of a factor does not result in reduction of the net present value to zero, the critical value of the net present value is

$$NPV^* = NPV(F^*) \quad (\text{Eq. 32})$$

where F^* is the maximum possible value of a factor.

Let us consider the determining of critical points if profitability index is used as a criterion of an investment project. At the same time, we are going to take into account the fact that the profitability index values should be at least 1.2.

The critical value of the initial investment can be found from the equation of the profitability index

$$PI^* = 1,2 = \frac{\sum_{i=1}^n \frac{R_0}{(1+d)^i}}{\left(I_0 + \frac{I_{aj}}{(1+d_{cr})^{T_j}} \right)} \quad (\text{Eq. 33})$$

So,

$$I_{cr} = \frac{\sum_{i=1}^n \frac{R_0}{(1+d)^i}}{PI^*} - \frac{I_{aj}}{(1+d_{cr})^{T_j}} \quad (\text{Eq. 34})$$

The critical value of the additional investment is

$$I_{ajcr} = (1 + d_{cr})^{T_j} \cdot \left(\frac{\sum_{i=1}^n \frac{R_0}{(1+d)^i}}{PI^*} - I_0 \right) \quad (\text{Eq. 35})$$

The critical value of the annual return is

$$R_{cr} = PI^* \cdot \frac{\left(I_0 + \frac{I_{aj}}{(1+d_{cr})^{T_j}} \right)}{\sum_{i=1}^n \frac{1}{(1+d)^i}} \quad (\text{Eq. 36})$$

The critical value of the economic plant life is to equal to the Discounted Payback Period (*DPP*)

$$T_{cr} = DPP = - \frac{\ln \left(1 - PI^* \cdot d \cdot \frac{I_0 + \frac{I_{aj}}{(1+d)^{T_j}}}{R_0} \right)}{\ln(1+d)} \quad (\text{Eq. 37})$$

Example of Sensitivity Analysis

In order to exemplify the sensitivity analysis, the below biogas plant project is used. The annual capacity of biogas plant is equal to 599,1 thousand m³. The initial data for different variants is listed in *Table 1*.

Table 1. Initial data for biogas plant project options

№	Parameters	Unit	Options		
			1	2	3
1	Initial investment	thousand EUR	765.22	884.78	913.48
2	Additional investment	thousand EUR	191.30	310.87	339.57
3	Period of additional investment	year	11.00		
4	Annual biogas production	thousand m ³	590.21		
5	Lifetime of project	year	20.00		
6	Discount rate		7.50		
7	Annual consumption of electricity by a biogas plant	thousand kWh	92.97		
8	Annual consumption of thermal energy by a biogas plant	thousand kWh	449.36		
9	Annual use of biogas to	thousand m ³	0.00	282.73	282.73

10	substitute diesel fuel Annual carbon dioxide production	thousand m ³	0.00	0.00	171.75
11	Company's annual electrical power consumption	thousand kWh	1146.96	0.00	0.00
12	Company's annual thermal energy consumption	thousand kWh	1029.86	0.00	0.00

To assess financial risks, we will use the above factors. The resulting calculations are demonstrated in *Table 2*.

Table 2. Project sensitivity analysis

№	Parameters	Relative deviation					
		Option 1		Option 2		Option 3	
		Critical change of a factor	Elasticity coefficient	Critical change of a factor	Elasticity coefficient	Critical change of a factor	Elasticity coefficient
1	Initial investment	0.61	-4.30	0.36	-6.55	1.58	-2.26
2	Additional investment	5.37	-1.37	2.27	-1.88	9.44	-1.21
3	Plant's economic life	-0.59	2.37	-0.52	2.88	-0.77	1.58
4	Discount rate	1.13	-2.77	0.84	-3.39	2.57	-1.78
5	Biogas plant-load factor	-0.35	4.67	-0.24	7.43	-0.58	2.47
6	Substrate cost value	1.45	-2.38	1.00	-3.00	4.53	-1.44
7	Operating expenses	0.76	-3.64	0.15	-14.62	0.58	-4.45
8	Electric energy use	-0.41	3.91	–	–	–	–
9	Thermal energy use	-0.99	1.03	–	–	–	–
10	Manure sale*	-1.00	0.90	-0.73	1.76	-1.00	0.54
11	Diesel fuel substitute	–	–	-0.12	15.51	-0.55	2.64
12	Carbon dioxide sale	–	–	–	–	-0.94	1.13

* Zero scope of manure use does not lead to a decrease in the net present value to zero in the first and third options.

The obtained data shows the main risk factors for the project:

- the first option – biogas is utilized to generate electric or/and heat power;
- the second and third options – biogas is used to substitute diesel fuel.

The projects' options prove to be stable to the value of an additional investment and substrate cost value. Use of the *PI* as a criterion for an investment project gives lower values of the input critical variables (*Table 3*).

Table 3. Comprehensive assessment of the project sensitivity

№	Parameters	Option 1		Option 2		Option 3	
		Critical change of a factor when using NPV	Critical change of a factor when using PI	Critical change of a factor when using NPV	Critical change of a factor when using PI	Critical change of a factor when using NPV	Critical change of a factor when using PI
1	Initial investment value	0.61	0.32	0.36	0.11	1.58	1.12
2	Additional investment value	5.37	2.86	2.27	0.67	9.44	6.68
3	Project lifetime	-0.59	-0.38	-0.52	-0.17	-0.77	-0.66
4	Biogas plant load factor	-0.35	-0.22	-0.24	-0.08	-0.58	-0.49

The sensitivity analysis of the project was carried out graphically. It is proposed to improve the classic method by introducing a line of the minimum allowable value project performance criteria ($NPV = 0$ or $PI = 1.2$). In percentage terms, the $NPV = -100\%$, while for the PI it is

$$\delta PI = \frac{PI^* - PI}{PI} \cdot 100\% \quad (\text{Eq. 34})$$

Fig. 3 shows that 20% decrease of return and 30% increase of investment cause critical reduction of PI . In the second option, 10% deviation of investment or return makes the project unprofitable (Fig. 4). The third option proves to be the most stable one (Fig. 5). The sensitivity analysis shows that the NPV and PI approximately respond to changes in the biogas plant capacity.

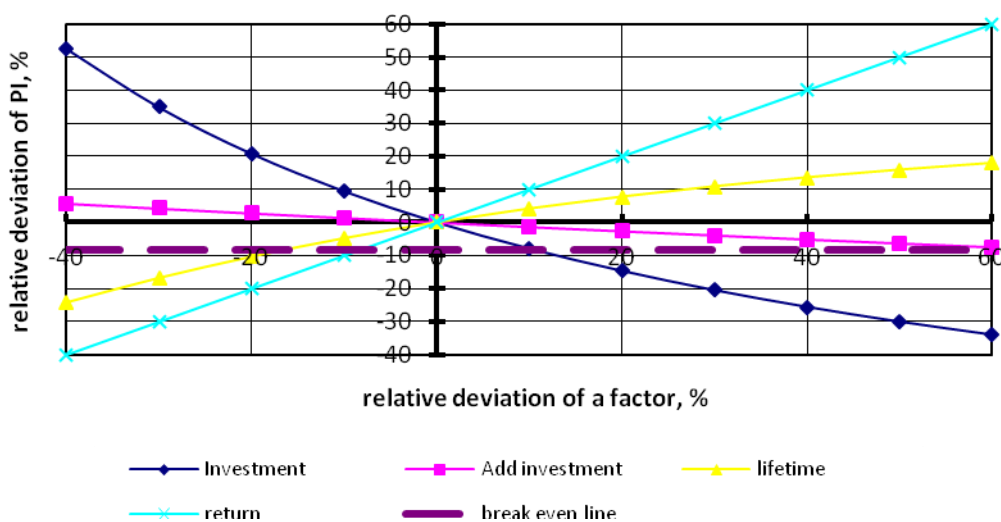

Figure 4. Sensitivity analysis of the second option

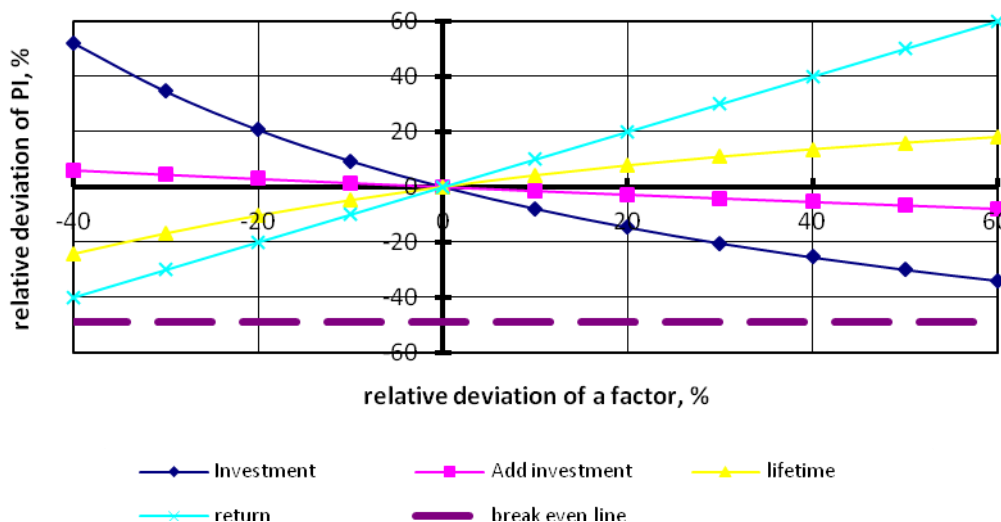

Figure 5. Sensitivity analysis of the third option

Conclusions

The profitability index is proposed to be used as a criterion of an investment project for the sensitivity analysis procedure. It can guarantee profitability of an investment project at the critical points. The economic and mathematical model for sensitivity analysis of an investment project of biogas plant has been developed. It takes into account the main input factors having influence on a project criterion.

According to the calculations for the biogas plant projects, the most risky option is to use biogas as vehicle fuel and not to use its by-product (carbon dioxide). The most sustainable project is using both biomethane (as vehicle fuel) and carbon dioxide for sale. This study has revealed that biogas plant projects are more sensitive to biogas

plant load factor, and less sensitive to the additional investment and substrate cost.

For further research, we suggest taking into account the scenario method to study probability of external factors. The sensitivity analysis methodology can be improved. The price ratio of biomethane and petroleum fuels should be subject to future study. Moreover, location and capacity have a high level of uncertainty.
